

NEUTRINO MASS: WHERE DO WE STAND, AND WHERE ARE WE GOING?*

BORIS KAYSER

We discuss the three major hints of neutrino mass: the strong evidence of mass from the behavior of atmospheric neutrinos, the very promising further hint from the behavior of solar neutrinos, and the so-far unconfirmed hint from the LSND experiment. Then, we describe two illustrative neutrino-mass scenarios suggested by the observed hints. We identify the needed future tests of both the present hints and the neutrino-mass scenarios.

1 Hints of Neutrino Mass

1.1 Atmospheric Neutrinos

The behavior of atmospheric neutrinos, produced in the earth's atmosphere by cosmic rays, now provides rather strong evidence that neutrinos have mass. The atmospheric neutrinos are studied by underground detectors. A signal that these neutrinos have mass is sought by looking for indications that they oscillate from one flavor to another—something they can do only if they have mass. The Super-Kamiokande underground experiment (Super K) has found evidence of this flavor oscillation which is particularly convincing because it is almost independent of theoretical input.¹ This persuasive evidence comes from the dependence of the detected atmospheric neutrino flux on the direction from which the neutrinos are coming.

Suppose that neutrinos do *not* oscillate, and consider the flux of neutrinos of a given flavor coming from polar angle θ with respect to the zenith—the point directly above the underground detector. Consider only neutrinos with energies above a few GeV, so that geomagnetic effects can be neglected. Then, given the fact that the flux of cosmic rays which produces the neutrinos in our atmosphere is isotropic,² it follows from a simple geometric argument that, at the detector, the neutrino fluxes from θ and $\pi - \theta$ will be equal³ to within a few percent.⁴ That is, the neutrino flux will be up-down symmetric.

By contrast, if neutrinos *do* oscillate, then in general the neutrino flux of a given flavor will *not* be up-down symmetric. In the usual approximation that only two neutrino flavors mix appreciably, the probability that a neutrino ν_f of flavor f (e, μ , or τ) will turn into one of a different flavor f' while traveling a distance L is given by

$$P(\nu_f \rightarrow \nu_{f' \neq f}) = \sin^2 2\alpha \sin^2 \left[1.27 \delta M^2 (\text{eV}^2) \frac{L(\text{km})}{E_\nu (\text{GeV})} \right]. \quad (1)$$

Here, E_ν is the neutrino energy, α is a mixing angle, and δM^2 is the difference between the squared masses of the two neutrino mass eigenstates that make up ν_f and $\nu_{f'}$. Now, since the Super K detector is not far below the earth's surface, downward-going neutrinos coming from $\theta \approx 0$, and thus produced in the atmosphere directly above the detector, travel only ~ 15 km to reach it. In contrast, upward-going neutrinos coming from $\theta \approx \pi$, and thus produced in the atmosphere on the opposite side of the earth from the detector, travel the entire diameter of the earth, $\sim 13,000$ km, to reach the detector. Let us suppose that $\delta M^2 \sim (\text{A Few}) \times 10^{-3} \text{ eV}^2$, and $E_\nu \sim \text{A Few GeV}$. Then, for the neutrinos from $\theta \approx 0$, $\delta M^2 (\text{eV}^2) \left[\frac{L(\text{km})}{E_\nu (\text{GeV})} \right] \ll 1$, while for the ones from $\theta \approx \pi$, $\delta M^2 (\text{eV}^2) \left[\frac{L(\text{km})}{E_\nu (\text{GeV})} \right] > 1$. Hence, from Eq. (1), upward-going neutrinos ν_f from $\theta \approx \pi$ can oscillate away into neutrinos of a new flavor before reaching the detector, while downward-going ones from $\theta \approx 0$ cannot. This distinction will result in a difference between the detected upward- and downward-going ν_f fluxes.

Now, what do the data show? Let us consider the Super K multi-GeV events, for which the visible energy deposition in the detector exceeds 1.33 GeV, and geomagnetic effects can be neglected. For these events, the ν_e flux is consistent with being up-down symmetric, but the ν_μ flux has a large up-down asymmetry. To be more quantitative, let us call the flux corresponding to $-1.0 < \cos \theta < -0.2$ “Up”, and the one corresponding to $+0.2 < \cos \theta < 1.0$ “Down”. Then,⁴ for the ν_e events,

$$\frac{\text{Up}}{\text{Down}} = 0.93^{+0.13}_{-0.12}, \quad (2)$$

but for the ν_μ events,

$$\frac{\text{Up}}{\text{Down}} = 0.54^{+0.06}_{-0.05}. \quad (3)$$

We see that Up/Down for the ν_μ events is very inconsistent with unity, the value it must have if there is no neutrino oscillation. Instead, Up/Down for these events suggests that the muon neutrinos which travel a signif-

*To appear in the Proceedings of the 29th International Conference on High Energy Physics, Vancouver, July 1998.

icant fraction of the earth's diameter to reach the detector (the "Up" flux) are oscillating away into another flavor, while the ones which travel only a short distance to reach the detector (the "Down" flux) are not. Since for this data sample $\langle E_\nu \rangle = \text{A Few GeV}$, we see from our previous discussion that a $\delta M^2 = \mathcal{O}(10^{-3} \text{ eV}^2)$ would produce this behavior. Since Up/Down for the ν_e events is consistent with unity, it appears that (at least most of) the muon neutrinos which oscillate away do not become electron neutrinos, but tau or sterile neutrinos, to which the detector is insensitive.⁵

The Super K detector cannot determine the L or the E_ν of an event accurately. However, estimating these quantities for each event as best as possible, the Super K experiment finds the L/E_ν distributions shown in Fig. 1.⁶ In this figure, the points show the ratios of observed event rates to Monte Carlo expectations in the absence of oscillations. The dashed lines show the expected shapes of

Figure 1: Observed ν_e and ν_μ event rates vs. L/E_ν .

these normalized event rates in the presence of $\nu_\mu \rightarrow \nu_\tau$ oscillation with $\delta M^2 = 2.2 \times 10^{-3} \text{ eV}^2$ and $\sin^2 2\alpha = 1$. Note that this oscillation hypothesis fits the data very nicely.

Together, the atmospheric neutrino data from Super K,¹ Soudan 2,⁷ and MACRO⁸ imply that the parameters of the $\nu_\mu \rightarrow \nu_\tau$ or $\nu_\mu \rightarrow \nu_{\text{sterile}}$ oscillation of the atmospheric neutrinos are

$$6 \times 10^{-4} \text{ eV}^2 \lesssim \delta M^2 \lesssim 10^{-2} \text{ eV}^2 \quad (4)$$

and

$$\sin^2 2\alpha \approx 1. \quad (5)$$

To confirm that the atmospheric neutrinos are oscillating, one would like to observe this same oscillation in an accelerator-generated ν_μ beam. To do that, one will have to allow the beam to travel a distance L which is not negligible compared to the earth's diameter, since $\delta M^2 \sim 10^{-3} \text{ eV}^2$, and the beam energy will not be less than $\sim 1 \text{ GeV}$. During the coming years, several such "long-baseline" accelerator neutrino oscillation searches will be performed, using beams generated at KEK, Fermilab, and CERN. It appears that this program of experiments will be able to look for oscillation with δM^2 down to $1 \times 10^{-3} \text{ eV}^2$, but not lower.^{9,10,11} It is unlikely that δM^2 lies below this value.^{7,4,8} However, it is not impossible. If δM^2 is indeed less than $1 \times 10^{-3} \text{ eV}^2$, then long-baseline experiments beyond those currently planned will probably be necessary. One intriguing possibility for an ultra-sensitive long-baseline oscillation search is to use a very intense neutrino beam which can be produced by the decay of the muons circulating in a future $\mu^+\mu^-$ collider.¹² Indeed, if one attaches to a $\mu^+\mu^-$ collider a small muon storage ring with a straight section pointed at a suitably distant neutrino detector, one can probably extend the δM^2 reach of a $\nu_\mu \rightarrow \nu_\tau$ search to $\mathcal{O}(10^{-4} \text{ eV}^2)$ at maximal mixing.¹³

1.2 Solar Neutrinos

Adding to the persuasive evidence of neutrino mass from the atmospheric neutrinos, the behavior of the solar neutrinos provides a strong further hint that neutrinos have nonzero masses. The observed solar neutrino ($\nu_\odot$) fluxes are all below Standard Solar Model (SSM) predictions.¹⁴ It has proved very difficult to explain these flux deficits by modifying the solar and/or nuclear physics assumed by the SSM, without invoking neutrino mass.^{15,16} We would like to give just one example of this difficulty: Owing to the relatively high $\nu_\odot$ energy threshold of the Super K detector, the only solar neutrinos seen by this detector are from ^8B decay. The Super K experiment finds that¹⁷

$$\frac{\phi(\nu_\odot \text{ from } ^8\text{B})|_{\text{Observed}}}{\phi(\nu_\odot \text{ from } ^8\text{B})|_{\text{SSM}}} = 0.47 \pm 0.08. \quad (6)$$

Now, the $\nu_\odot$ flux produced by ^8B decay depends very sensitively on T_{core} , the temperature in the core of the sun: $\phi(\nu_\odot \text{ from } ^8\text{B}) \propto T_{\text{core}}^{24}$. Thus, it is tempting to suppose that the low observed ^8B flux may be due simply to a T_{core} slightly below that in the SSM. However, helioseismology now tells us that $T_{\text{core}} \geq 0.998 T_{\text{core}}|_{\text{SSM}}$.¹⁸ Using $\phi(\nu_\odot \text{ from } ^8\text{B}) \propto T_{\text{core}}^{24}$, it follows that $\phi(\nu_\odot \text{ from } ^8\text{B}) \geq 0.95 \phi(\nu_\odot \text{ from } ^8\text{B})|_{\text{SSM}}$. That is, by simply lowering T_{core} from its SSM value by the tiny amount allowed by helioseismology, one cannot come close to explaining the $\sim 50\%$ shortfall in the observed ^8B flux.

By contrast, if we do invoke neutrino mass, then the observed $\nu_\odot$ fluxes can be explained successfully and elegantly. If neutrinos have mass, then a ν_e —the type of neutrino generated in the center of the sun, and to which present solar neutrino detectors are sensitive—can convert into another type of neutrino, ν_x , to which these detectors are completely, or at least largely, insensitive. The ν_x may be a ν_μ , ν_τ , or sterile neutrino ν_S . Perhaps the most appealing $\nu_e \rightarrow \nu_x$ conversion mechanism is the Mikheyev, Smirnov, Wolfenstein (MSW) effect. In this effect, the $\nu_e \rightarrow \nu_x$ conversion results from the crossing, somewhere in the sun, of the total energy levels of ν_e and ν_x . Since the ν_e has a charged-current interaction with solar electrons, its total energy in the sun includes not only its free-particle energy, $\sqrt{p_\nu^2 + M_{\nu_e}^2}$, but also a $\nu_e - e$ interaction energy, $\sqrt{2} G_F N_e$. Here, p_ν is the neutrino momentum, M_{ν_e} is the mass of ν_e , G_F is the Fermi constant, and N_e is the solar electron density. In contrast to the ν_e , the $\nu_x (= \mu, \tau, \text{or } S)$ does not have a charged-current interaction with electrons, so its total energy in the sun, for the given p_ν , is simply $\sqrt{p_\nu^2 + M_{\nu_x}^2}$. The level crossing condition is then

$$\sqrt{p_\nu^2 + M_{\nu_x}^2} = \sqrt{p_\nu^2 + M_{\nu_e}^2} + \sqrt{2} G_F N_e. \quad (7)$$

In the sun, $p_\nu \sim 1$ MeV and N_e is characteristically $10^{26}/\text{cc}$, so for this condition to be satisfied, we require a mass splitting

$$M_{\nu_x}^2 - M_{\nu_e}^2 \equiv \delta M_{\nu_x \nu_e}^2 \sim 10^{-5} \text{ eV}^2. \quad (8)$$

It is found that when the MSW effect is invoked, there are two regions in $(\sin^2 2\alpha_{\nu_x \nu_e}, \delta M_{\nu_x \nu_e}^2)$ space that fit the $\nu_\odot$ data.¹⁹ One has $\sin^2 2\alpha_{\nu_x \nu_e} \sim 4 \times 10^{-3}$ and the other $\sin^2 2\alpha_{\nu_x \nu_e} \sim 0.8$. For the reason just explained, both have $\delta M_{\nu_x \nu_e}^2 = \mathcal{O}(10^{-5} \text{ eV}^2)$.

The $\nu_\odot$ data can also be explained assuming that it is two-flavor neutrino oscillation in vacuum, taking place between the sun and the earth and described by Eq. (1), that causes the $\nu_e \rightarrow \nu_x$ conversion of the solar neutrinos.^{20,16} To account in this manner for the event rates observed in all the $\nu_\odot$ experiments, one requires that (cf. Eq. (1))

$$\delta M^2 \frac{L}{E_\nu} \sim 1, \quad (9)$$

where now L is the distance from the sun to the earth, and $E_\nu \sim 1$ MeV is the energy of a typical solar neutrino. One may feel that for δM^2 to be such that Eq. (9) is satisfied when L is the distance from the sun to the earth demands a somewhat implausible coincidence. Be that as it may, the δM^2 that does the job is

$$\delta M^2 \sim 10^{-(9-11)} \text{ eV}^2. \quad (10)$$

To fit the data, the mixing angle is

$$0.7 \lesssim \sin^2 2\alpha \lesssim 1.0. \quad (11)$$

If, either through the MSW effect or oscillation in vacuum, solar electron neutrinos are being converted into muon or tau neutrinos, then obviously one would like to confirm the presence of these muon or tau neutrinos in the solar neutrino flux. An experiment which will be able to see them is being constructed in Canada. However, it is possible that the solar electron neutrinos are being converted, not to muon or tau neutrinos, but to sterile ones. Thus, the presence or absence of a ν_μ or ν_τ component in the solar flux is not a completely sure-fire test of solar neutrino flavor conversion.

Whether such conversion occurs via the MSW effect or vacuum oscillation, its probability is, in general, energy dependent. Thus, it distorts the energy spectrum of solar electron neutrinos which retain their original flavor. Clearly, one would like to observe this distortion. The Super K experiment has already obtained some early information on the energy spectrum.¹⁷ It will be interesting to see what further spectral studies will show.

Additional confirmation of solar neutrino flavor conversion would come from observation of a day/night or seasonal variation in the solar ν_e flux. The “day/night effect” could be greatly enhanced for neutrinos passing through the earth’s core.²¹

1.3 LSND

A third, so far unconfirmed, hint of neutrino mass comes from the Liquid Scintillator Neutrino Detector (LSND) at Los Alamos. Studying the $\bar{\nu}_\mu$ flux from μ^+ decay at rest, LSND finds evidence for the appearance of $\bar{\nu}_e$, signalling the occurrence of the oscillation $\bar{\nu}_\mu \rightarrow \bar{\nu}_e$.²² Studying the ν_μ flux from the decay $\pi^+ \rightarrow \mu^+ \nu_\mu$ of positive pions in flight, this experiment finds evidence for the appearance of ν_e , signalling the occurrence of $\nu_\mu \rightarrow \nu_e$.²³ Since $L/E_\nu \sim 30 \text{ m}/30 \text{ MeV}$ in LSND, we see from Eq. (1) that we must have $\delta M^2 \gtrsim 1 \text{ eV}^2$ to account for the observed oscillations. More specifically, the $(\bar{\nu})_\mu \rightarrow (\bar{\nu})_e$ interpretation of the LSND data favors

$$0.2 \text{ eV}^2 \lesssim \delta M^2 \lesssim 10 \text{ eV}^2 \quad (12)$$

and

$$0.002 \lesssim \sin^2 2\alpha \lesssim 0.03. \quad (13)$$

A number of other experiments have placed upper bounds on $(\bar{\nu})_\mu \rightarrow (\bar{\nu})_e$ oscillation.²⁴ Together, the KARMEN 2 and Bugey bounds allow only a narrow sliver of the $(\delta M^2, \sin^2 2\alpha)$ region favored by LSND. However, KARMEN 2 anticipated seeing three background events, and in fact saw no events—background or signal. Had KARMEN 2 seen the expected three background events,

this experiment, plus all the others with bounds, would have allowed a good deal of the LSND-favored region. Thus, the situation with respect to the LSND oscillation signal appears to be somewhat unsettled. It is important to confirm or disprove the $(\bar{\nu})_\mu \rightarrow (\bar{\nu})_e$ interpretation of the LSND data through future studies. These studies will be carried out both by KARMEN and by a new experiment at Fermilab.

2 Hot Dark Matter

Evidence is accumulating that

$$\Omega_M = 0.1 - 0.4, \quad (14)$$

rather than unity.^{25,26} Here, Ω_M is the total mass density of the universe, as a fraction of the critical density required to stop indefinite expansion. Now, much of the Ω_M of Eq. (14) is dark, and some of this dark matter *might* be Hot Dark Matter (HDM); that is, dark matter consisting of particles whose masses are small compared to 1 keV. Neutrinos are natural candidates for such particles. However, some of the dark matter must be Cold Dark Matter (CDM), consisting of particles much heavier than neutrinos, because these heavier particles were needed to seed the early-universe formation of the observed galactic structure. If $\Omega_M \lesssim 0.4$, and the mass density of CDM is, say, at least 0.2, then the mass density of HDM, Ω_{HDM} , obeys the constraint

$$\Omega_{HDM} \lesssim 0.2. \quad (15)$$

The relation between the masses M_{ν_m} of the neutrino mass eigenstates ν_m and the mass density Ω_ν in neutrinos is

$$M_{\nu_1} + M_{\nu_2} + M_{\nu_3} = \Omega_\nu (33 \text{ eV}). \quad (16)$$

Here, we are assuming that there are only three mass eigenstates, which make up ν_e , ν_μ , and ν_τ . Now, if neutrinos are light compared to 1 keV, as certainly appears to be the case, then $\Omega_\nu \leq \Omega_{HDM}$. Then, Eqs. (15) and (16) imply that

$$M_{\nu_1} + M_{\nu_2} + M_{\nu_3} \lesssim 6 \text{ eV}. \quad (17)$$

This condition is not a hint of neutrino mass, but a *constraint* on neutrino mass.

3 Where Does the Evidence Point?

We have discussed the evidence for neutrino mass from the behavior of atmospheric neutrinos, the major further hint of mass from the behavior of solar neutrinos, and the unconfirmed additional hint from the LSND experiment. To what neutrino mass scenarios do these hints point?

Suppose that the atmospheric, solar, and LSND neutrinos all oscillate. The observed “frequencies” δM^2 of these three oscillations cannot all be accommodated in any simple way in terms of the masses of just the three mass eigenstate neutrinos making up ν_e , ν_μ , and ν_τ . If there are only three mass eigenstate neutrinos, ν_1 , ν_2 , and ν_3 , then there are just three different splittings $\delta M_{\nu_i \nu_j}^2 \equiv M_{\nu_i}^2 - M_{\nu_j}^2$, and these three splittings obviously satisfy

$$\begin{aligned} \sum_{\text{Splittings}} \delta M_{\nu_i \nu_j}^2 &= (M_{\nu_3}^2 - M_{\nu_2}^2) + (M_{\nu_2}^2 - M_{\nu_1}^2) \\ &\quad + (M_{\nu_1}^2 - M_{\nu_3}^2) \\ &= 0. \end{aligned} \quad (18)$$

But, as we have seen, the splittings required by the three hints of oscillation are approximately as summarized in Table 1. Since the δM^2 values required by the three hints

Table 1: Mass splittings required by the three hints of oscillation.

Oscillating Neutrinos	Required $ \delta M^2 $ (eV ²)
Solar	10^{-10} or 10^{-5}
Atmospheric	10^{-3} to 10^{-2}
LSND	10^{-1} to 10^{+1}

are, respectively, of three different orders of magnitude, there is no way they can add up to zero, as demanded by Eq. (18), no matter which sign we assign to each of them. Thus, just three neutrinos cannot explain the observed three hints of oscillation.²⁷ To accommodate all three of these hints, we must introduce (at least) a fourth neutrino. Since we know from the width of the weak boson Z^0 that only three species of neutrinos have normal electroweak interactions, the extra, fourth neutrino must be a sterile neutrino ν_S .

If one is uneasy about introducing a light sterile neutrino, then he can proceed by provisionally setting aside the so-far unconfirmed LSND result, and attempting to explain only the atmospheric and solar neutrino results in terms of neutrino oscillation. One can then have the neutrino mass spectrum shown in Fig. 2. There, ν_1 , ν_2 , and ν_3 are the mass eigenstates. The flavor content of each of these is indicated by dotting and hatching: The ν_e fraction of a mass eigenstate is dotted, the ν_μ fraction is indicated by right-leaning hatching, and the ν_τ fraction by left-leaning hatching.²⁸ The masses in Fig. 2 form a hierarchy: $M_{\nu_3} \gg M_{\nu_2} \gg M_{\nu_1}$. The mass-squared splitting $M_{\nu_3}^2 - M_{\nu_2}^2 \simeq M_{\nu_2}^2 \simeq 10^{-3} \text{ eV}^2$ gives the atmospheric neutrino oscillation, while the splitting $M_{\nu_2}^2 - M_{\nu_1}^2 \simeq M_{\nu_1}^2 \simeq 10^{-5} \text{ eV}^2$ yields the MSW effect in the sun.

Figure 2: A three-neutrino mass hierarchy that accounts for the oscillations of atmospheric and solar neutrinos.

The hierarchy in Fig. 2 is the lightest one which gives the δM^2 values required by the atmospheric and solar oscillations. Since oscillations determine only mass splittings, and not actual masses, one, of course, can increase the masses in Fig. 2 without affecting the oscillations so long as one keeps the δM^2 values fixed. For example, if neutrinos contribute significantly to Ω_M , then perhaps $M_{\nu_1} \simeq M_{\nu_2} \simeq M_{\nu_3} \simeq (1-2) \text{ eV}$, with the δM^2 values as in Fig. 2.

If one accepts the inclusion of a ν_S among the light neutrinos, then all three hints of oscillation can be accommodated. One neutrino mass spectrum which does this is shown in Fig. 3.²⁹ In this spectrum there are, of

Figure 3: A four-neutrino scenario that accounts for the oscillations of the atmospheric, solar, and LSND neutrinos. In this scenario, the mass eigenstate ν_0 is largely a sterile neutrino ν_S . The $\sim 1 \text{ eV}$ neutrinos in the scheme make a significant contribution to Hot Dark Matter.

course, four mass eigenstates, $\nu_0 - \nu_3$. The ν_e , ν_μ , and ν_τ fractions of these mass eigenstates are indicated as they were in Fig. 2, and the ν_S fraction is shown as a clear region. There are two $\sim 1 \text{ eV}$ mass eigenstates, ν_2 and ν_3 , with a mass splitting $\delta M^2 \sim 10^{-3} \text{ eV}^2$ that yields the atmospheric neutrino oscillation. Then there are two much lighter mass eigenstates, ν_0 and ν_1 , with a splitting $\delta M^2 \sim 10^{-5} \text{ eV}^2$ that gives the MSW effect in the sun.

However, from Fig. 3 we see that in this scheme the MSW effect converts a ν_e into a *sterile* neutrino, rather than a muon or tau neutrino. Thus, there is no ν_μ or ν_τ component in the solar neutrino flux. Finally, the splitting $\delta M^2 \sim 1 \text{ eV}^2$ between the heavy pair ν_2 and ν_3 , and the light pair ν_0 and ν_1 , produces the LSND oscillation. The heavy pair in this scenario has the smallest average mass, $\sim 1 \text{ eV}$, which can still yield the $\delta M^2 \sim 1 \text{ eV}^2$ called for by LSND. Interestingly, this $\sim 1 \text{ eV}$ mass has the consequence that the members of this pair make a significant hot dark matter contribution to the mass density of the universe, but without violating the cosmological upper bound of Eq. (17) on neutrino mass.

In theories of neutrino mass, sterile neutrinos occur commonly and naturally. However, these sterile neutrinos tend to be heavy, with masses in the multi-GeV range or higher. *Light* sterile neutrinos, with masses of 1 eV or less, are not generally anticipated. Confirmation of the existence of a light sterile neutrino such as the one required by the scenario of Fig. 3 would be as groundbreaking a finding as the original discovery of neutrino mass. Thus, it is very important to carry out the future experiments which will test the oscillation interpretations of the atmospheric, solar, and LSND results, and to thoroughly examine the question of whether or not these three oscillations, if all confirmed, together require the existence of a fourth, sterile neutrino.

The two neutrino-mass scenarios we have discussed are just examples. Other scenarios are possible. The candidate scenarios can be tested through future experiments. For example, the three-neutrino scheme of Fig. 2 predicts a $\nu_{\mu,\tau}$ component in the solar neutrino flux, while the four-neutrino scheme of Fig. 3 predicts none. The four-neutrino scheme predicts the confirmation of LSND, while the three-neutrino one predicts its disproof. Both scenarios predict a distortion of the energy spectrum of electron neutrinos from the sun, and other phenomena as well.

4 Conclusion

Thanks to the strong atmospheric-neutrino evidence that neutrinos do have nonzero masses, this is without question an exciting time in neutrino physics. What we need now are further strong signals that neutrinos have mass, and more insight—experimental and theoretical—into the masses and mixings chosen by nature.

27. This argument assumes that each of the three oscillations may be described by just a single δM^2 . There have been interesting attempts (R. Thun and S. McKee, hep-ph/9806534; T. Teshima and T. Sakai, hep-ph/9805386; C. Cardall and G. Fuller, talk presented by C. Cardall at the 1998 Aspen Winter Conference on Particle Physics, held in Aspen, CO, January 1998) to fit all three oscillations with just three neutrinos by dropping this simple assumption. However, it appears to us that every such attempt is in some conflict with *some* of the oscillation data.
28. We owe this general approach to depicting neutrino-mass scenarios to A. Smirnov, in *Proc. 28th Int. Conf. on High Energy Physics*, edited by Z. Ajduk and A. Wroblewski (World Scientific, Singapore, 1997) p.288.
29. This is a somewhat modified version of a neutrino-mass scenario proposed in D. Caldwell and R. Mohapatra, *Phys. Rev. D* **48**, 3259 (1993). See also V. Barger, S. Pakvasa, T. Weiler, and K. Whisnant, hep-ph/9806328.
